# Foreword

Tsunamis have been recognized as a potential hazard to United States coastal communities since the mid-twentieth century, when multiple destructive tsunamis caused damage to the states of Hawaii, Alaska, California, Oregon, and Washington. In response to these events, the United States, under the auspices of the National Oceanic and Atmospheric Administration (NOAA), established the Pacific and Alaska Tsunami Warning Centers, dedicated to protecting United States interests from the threat posed by tsunamis. NOAA also created a tsunami research program at the Pacific Marine Environmental Laboratory (PMEL) to develop improved warning products.

The scale of destruction and unprecedented loss of life following the December 2004 Sumatra tsunami served as the catalyst to refocus efforts in the United States on reducing tsunami vulnerability of coastal communities, and on 20 December 2006, the United States Congress passed the "Tsunami Warning and Education Act" under which education and warning activities were thereafter specified and mandated. A "tsunami forecasting capability based on models and measurements, including tsunami inundation models and maps" is a central component for the protection of United States coastlines from the threat posed by tsunamis. The forecasting capability for each community described in the PMEL Tsunami Forecast Series is the result of collaboration between the National Oceanic and Atmospheric Administration office of Oceanic and Atmospheric Research, National Weather Service, National Ocean Service, National Environmental Satellite Data and Information Service, the University of Washington's Joint Institute for the Study of the Atmosphere and Ocean, National Science Foundation, and United States Geological Survey.

NOAA Center for Tsunami Research

## **Abstract**

The present study documents the development of a tsunami forecast model for the U.S. territory of Wake Island. Despite the small relevance of Wake Island as a population center, and its decreasing strategic importance in today's political landscape, the island remains an important reference point for tsunami forecasters. Due to its geographical location, unique topography, and its large distance to any continental platform that could interfere with a tsunami signal, the tide gauge on Wake Island can provide a clean and distinct signal of a tsunami in deep water. In order to guarantee the accuracy, robustness, and stability of the forecast model in an operational environment, 10 historical events have been simulated and results compared with tide gauge observations when these data were available. Additionally, the robustness of the model to very large events has been tested by simulating 18 synthetic,  $M_w=9.3$  events originating at different subduction zones in the Pacific. Results from both the historical and synthetic simulations show that Wake Island is particularly protected from tsunami impact. This may be due to the fact that the island is not located in the main beam of any of the events simulated and also to the absence of a continental shelf that could generate strong wave shoaling.

# Chapter 1

## Background and Objectives

The Pacific Marine Environmental Laboratory (PMEL) of the National Oceanic and Atmospheric Administration (NOAA) Center for Tsunami Research (NCTR) has developed a tsunami forecasting capability for operational use by NOAA's two Tsunami Warning Centers located in Hawaii and Alaska (Titov et al., 2005). The system is designed to efficiently provide basin-wide warning of approaching tsunami waves. The system, termed Short-term Inundation Forecast of Tsunamis (SIFT), combines real-time tsunami event data with numerical models to produce estimates of tsunami wave arrival times and amplitudes at a coastal community of interest. The SIFT system integrates several key components: deep-ocean, real-time observations of tsunamis, a basin-wide pre-computed propagation database of water level and flow velocities based on potential seismic unit sources, an inversion algorithm to refine the tsunami source based on deep-ocean observations during an event, and optimized tsunami forecast models.

Wake Island is an unincorporated territory of the U.S. located approximately 3,700 km (2,300 mi) west of the Hawaiian Islands. Its use is restricted to military operations and there are no indigenous or permanent residents on the island.

The first U.S. settlement on Wake Island dates back to 1899 when the island was selected for the site of a cable station. Following that, the island served as an air and naval base to the U.S. military until World War II, when Wake Island was temporarily captured by the Japanese, only to return to U.S. control after the war. The U.S. built aircraft landing facilities on the island to serve as an emergency landing site for aircraft flying over the Pacific. In August 2006, Wake Island was evacuated of military and civilian personnel due to the approach of category 5 typhoon Ioke. The effects of the typhoon on the island halted subsequent operations. A small group of contractors and military personnel has since returned to the island to conduct clean up and restoration tasks (source: Central Intelligence Agency World Fact Book, 2014).

Wake Island was one of the locations selected for the development of a tsunami warning model because, despite the limited human presence on the island, its low-lying topography makes it nearly impossible for any island residents to find shelter from large tsunami waves. A tsunami forecast model for the island would provide residents with timely and vital information to determine the best course of action in the event of a tsunami.

It can also be argued that the location of Wake Island, with its unique and deep bathymetric surroundings, provides an ideal opportunity for the Tsunami Warning Centers to gauge propagating tsunami waves in deep water. In this regard, the absence of a continental shelf or any other surrounding islands will minimize the interaction of the tsunami wave with the local bathymetry, allowing the island's tide gauge to perform almost as an additional Deep-water

Assessment and Reporting of Tsunamis (DART®) system.

The existence of a National Ocean Service tide gauge on the island, established on 29 May 29 1950 and operated by a National Weather Service office located at the U.S. Army base, is crucial for the development of a tsunami forecast model, since it provides historical data for model validation and the possibility of quantitative assessment of model accuracy and performance in future events.

This report details the development of a high-resolution tsunami forecast model for Wake Island, including development of the bathymetric grids, model validation with historic events, and stability testing with a set of synthetic mega-tsunami (Mw 9.3) events. Inundation results from such events are also presented in later sections.

## **Chapter 2**

# **Forecast Methodology**

A high-resolution inundation model was used as the basis for the operational forecast model to provide an estimate of wave arrival time, height, and inundation immediately following tsunami generation. Tsunami forecast models are run in real time while the tsunami in question is propagating across the open ocean. These models are designed and tested to perform under very stringent time constraints, given that time is generally the single limiting factor in saving lives and property. The goal is to maximize the amount of time that an at-risk community has to respond to the tsunami threat by providing timely and accurate information.

The tsunami forecast model, based on the Method of Splitting Tsunami (MOST), emerges as the solution in the SIFT system by modeling real-time tsunamis in minutes while employing high-resolution grids constructed by the National Geophysical Data Center (NGDC) or, in limited instances, internally. Each forecast model consists of three telescoped grids with increasing spatial and temporal resolution for simulation of wave inundation onto dry land. The forecast model utilizes the most recent bathymetry and topography available to reproduce the correct wave dynamics during the inundation computation. Forecast models are constructed for at-risk populous coastal communities in the Pacific and Atlantic oceans. Previous and present development of forecast models in the Pacific (Titov et al., 2005; Titov, 2009; Tang et al., 2009; Wei et al., 2008) have validated the accuracy and efficiency of the forecast models currently implemented in the SIFT system for real-time tsunami forecast. The system is also a valuable tool in hindcast research. Tang et al. (2009) provides forecast methodology details.

# **Chapter 3**

# **Model Development**

Modeling of coastal communities is accomplished by development of a set of three nested grids that telescope down from a large spatial extent to a grid that finely defines the localized community. The basis for these grids is a high-resolution digital elevation model (DEM) constructed by either NCTR or, more commonly, by NGDC using best available bathymetric, topographic, and coastal shoreline data for an at-risk community. For each community, data are compiled from a variety of sources to produce a digital elevation model referenced to Mean High Water in the vertical and to the World Geodetic System 1984 in the horizontal (<http://ngdc.noaa.gov/mgg/inundation/tsunami/inundation.html>). From these digital elevation models, a set of three high-resolution reference models are constructed and then "optimized" to run in an operationally specified period of time.

The bathymetry and topography used in the development of this forecast model was based on a digital elevation model provided by the NGDC and the author considers it to be an adequate representation of the local topography/bathymetry. As new digital elevation models become available, forecast models will be updated and report updates will be posted at [http://nctr.pmel.noaa.gov/forecast\\_reports](http://nctr.pmel.noaa.gov/forecast_reports).

## **3.1 Forecast area**

Wake Island is an atoll comprised of three islets in the central Pacific Ocean. The three islets Wilkes, Peale, and Wake are connected by causeways and sit on a 7.2 km (4.5 mile) long, 3.2 km (2 mile) wide reef enclosing a lagoon that is also the crater of an underwater volcano. Their total land area is 6.5 square km (2.5 square miles) and the maximum elevation is 6 meters (21 feet) above sea level. Figure 1 is a map of Wake Island, showing the relative position of the three islets and the location of the island's tide gauge between Wilkes and Wake Island. (Encyclopedia Britannica, 2014)

## **3.2 Historical events and data**

The tide gauge on Wake Island was installed on 29 May 1950 and re-deployed at its current location (166.6177° E, 19.2906° N) along the small boat channel on the southern coast of the island on 20 January 1989. Acceptable quality data from the Wake Island tide gauge were found for 4 of the 10 historic events (see Table 1), used in the validation of the tsunami model for the

island: 1994 Kuril, 1996 Andreanof, 2006 Kuril, and 2007 Kuril. For the other events listed in Table 1, the data were either not available or the signal-to-noise ratio of the time series was too low to accurately identify the tsunami. The original time series were then band-passed filtered between periods of 2 min to 2.5 hr using a Butterworth filter. This frequency band captures tsunami waves while discarding higher frequency components due to the effect of ocean swell and lower frequencies associated with tidal oscillations.

The results of modeling a large number of events in Wake Island suggest that the island is relatively well protected from tsunami inundation. This may be due to its small size and deep bathymetric surroundings or to the presence of a coral reef that almost completely encloses the island, but most likely to a combination of both of these. Few of the tested events and none of the historical ones have caused significant inundation on the island. Moreover, neither of the two largest historical events in the Pacific Ocean since the inception of tide gauge operations at Wake Island, the 1960 Chile and 1964 Gulf of Alaska events, showed large tsunami waves at the gauge. Waves from the 1964 event were on the order of 20–30 cm (peak-to-trough), whereas those for the 1960 event show maximum wave heights of approximately 80 cm. These two events have not been included in the list of simulated historical tsunamis due to the lack of reliable tsunami sources for them; however, their recorded tide gauge data are presented in Figures D.1 and D.2 Supplementary Material (Appendix D) for reference.

### 3.3 Model setup

Setup of the computational grids for the MOST code (Titov, 1998) requires a total of three nested grids for which the outer grid A has the lowest spatial resolution, but covers the largest area, and the inner grid C has the highest spatial resolution, but covers a reduced geographical area. The code makes use of an additional intermediate grid B with medium resolution and spatial coverage. Each interior grid is fully enclosed in the area covered by its immediate exterior grid, and inundation is computed only in the innermost grid (Grid C). The purpose of the set of three nested grids is to ensure that as the tsunami wavelength shrinks when it travels from deep to shallow waters, the model maintains an approximately constant number of grid nodes per wavelength.

During the development of an operational forecast model, a higher-resolution set of grids, referred to as the reference model, is generated first. The purpose of the reference model is to evaluate grid convergence between a high-resolution model and the forecast model, ensuring that the solution obtained with the lower-resolution forecast model is consistent with that computed with the high-resolution reference model.

In the case of Wake Island, due to the absence of a continental shelf, the tsunami will most likely not shorten its wavelength significantly until it reaches the immediate vicinity of the island. Because there are no neighboring coastlines for the tsunami to interact with, there is, therefore, no need for extensive area coverage with A or B grids. However, due to the presence of a shallow coral reef, responsible for the generation of high-frequency waves surrounding the island, the resolution of grid B was kept relatively high (3 arc seconds), even in the forecast model. An effort was made to include almost the entire island within the C grid of the forecast model; however, due to the large area covered by the island and its surrounding reef, the need to maintain a relatively high grid resolution, and the limited amount of processing time to execute an operational forecast model, a decision was made to center the forecast grid C around

the tide gauge location, resulting in the exclusion of part of the coral reef on the western side of the island.

Because reference grid A was designed with smaller coverage than normal due to the absence of a continental shelf, the same grid A was used for both the reference and forecast model without any modification.

Figure 2 shows an aerial view of Wake Island, and Figures 3 and 4 show grid areas and relative position with respect to the island for the reference and forecast models, respectively. Table 2 summarizes the parameters and model setup for each set of grids.

The original bathymetric and topographic grid data used in the development of the Wake Island model were provided by NGDC. Details of data gathering and grid construction techniques used by NGDC in the generation of the original grid are provided by Medley et al. (2009).

# **Chapter 4**

## **Results and discussion**

Three types of tests were performed to assess the forecast model convergence, accuracy, and robustness characteristics. To assess model convergence, results obtained with the reference model were compared with those obtained with the forecast model to confirm consistency of results, at least for the leading tsunami waves. This type of test is not, strictly speaking, a grid convergence test such as is used in computational science, since the solution is compared using grids with varying resolution, coverage, and bathymetric information; however, it provides a good estimate of the similarities and discrepancies between the solutions of a more accurate, high-resolution reference model of the area and that of a coarser-resolution run-time optimized forecast model.

The accuracy of both the reference and forecast models is evaluated by comparing modeled and recorded data for a set of historical events.

Robustness tests include the simulation of 18 tsunamis generated by Mw 9.3 earthquakes throughout the Pacific Basin and a single micro-tsunami event ( $\alpha = 0.1$ ). Figures 5 and 6 show the epicenter of the historical events and center of the rupture segment for each of these synthetic events, respectively. The forecast model was verified to run smoothly, without instabilities during 24 hours of simulation for each of these mega-tsunami events.

### **4.1 Model validation**

Model validation using historical events is typically done by comparing the modeled signal with the signal recorded by the tide gauge. In the case of Wake Island, the tide gauge is located in a small boat harbor on the south side of the island. The harbor is connected to the open ocean by an approximately 30 m wide, 450 m long channel. Tsunami wave dynamics were hard to capture inside the small boat harbor even at 1/3-arc sec (~10 m) reference grid resolution, most likely due to the difficulty in representing the narrow channel. At forecast model resolution of one arc sec (~30 m), no more than one grid node is available to capture the width of the channel. To ensure accuracy of model prediction at the tide gauge location, an additional time series located outside the small boat harbor at the entrance of the channel (166.6140° E, 19.2895° N), and referred to henceforth as sample point 2, was selected for comparison.

Comparison results at the tide station for the reference and forecast models are presented in Figures 7 through 16, with Figures 8, 9, 12, and 13 also displaying tide gauge data for those events. Plots of the comparison at sample point 2 are shown in Figures D.3 through D.12 in

Supplementary Material (Appendix D). The results reflect an almost peak-to-peak agreement between the forecast and reference models in most cases. This comparison is particularly good in water level signals taken at sample point 2. The largest discrepancies between the reference and forecast models resulted from the 1946 Unimak event, showing approximately 20% discrepancy in the maximum amplitude of the signal, but almost peak-to-peak correlation even in later waves, and the 2007 Kuril, 2003 Rat Island, and 2006 Tonga events, with good maximum amplitude correlation, but some discrepancies in the simulation of later waves.

The accuracy of both the forecast and reference model was examined for the 1994 Kuril, 1996 Andreanof, 2006 Kuril, and 2007 Kuril in Figures 8, 9, 12, and 13. For all of these cases but the 2006 Kuril event, both the reference and model series were able to capture the arrival time, wave period, and overall magnitude of the event. Results for the 2006 Kuril event showed wave amplitudes approximately half the size of those recorded at the tide gauge.

In addition to tide gauge comparisons, maximum sea level elevation at each point on the grid for every event simulated were computed and compared between the reference and forecast models. Figures 17 through 26 show similarities and discrepancies between models for each of the 10 historical scenarios used. In general, agreement on the southern section of the island was very good. However, the area surrounding the entrance channel to the internal lagoon and separating Peale Island from Wake Island seems to display consistently low values in the forecast runs when compared with the reference runs. A possible solution to this effect could be the extension of the intermediate grid B further north, but this possibility has not been investigated.

## 4.2 Model stability testing using synthetic scenarios

During model stability testing, 18 mega-tsunami (Mw 9.3) events were simulated using the forecast model. Details of the 18 synthetic events tested can be found in Table 3. Each of these extreme synthetic events is constructed along a 1000 km long x 100 km wide fault plane with uniform slip amount of 29 m along the fault. The output from the code at every time step was visualized and inspected for instabilities. The cause of any instability was corrected and a final set of forecast grids emerged from the process. As in the case of historical events, the maximum water elevation at every point in the computational grid was recorded for each scenario. Although the original purpose of the stability tests is not to provide hazard assessment for the island, it is important to notice that the maximum wave height tends to occur inside the small boat harbor. The highest sea level elevation recorded at this point was 1.4 m (wave amplitude), originating in the Kuril Islands. None of the mega-tsunami events tested on the grids generated substantial flooding on the island. Results are presented in Figures 27 to 44. Time series of the tsunami signal at the Wake Island's tide gauge for the 18 synthetic Mw 9.3 events can be found in Figures D13 through D15 in Appendix D.

In addition to the 18 Mw 9.3 events, the stability of the model to a micro-tsunami (Mw 6.8) event is also tested by making sure that no spurious oscillations develop during the simulation of a small tsunami. For this particular study, the small event was selected off the coast of Chile and was generated by rupture of a single unit source with a slip amount of 0.1 m. This source appears listed in Table 3 as synthetic case 19. During the simulation of this event, no spurious oscillations were observed. Results showing the maximum water elevation at every point for this event are reflected in Figure 45.

## **Chapter 5**

# **Summary and conclusions**

A set of tsunami forecast grids for Wake Island have been developed for operational use by the Tsunami Warning Centers. Two sets of grids were developed: a high-resolution set intended to provide reference values, and a forecast set designed to minimize processor run time and to provide real-time tsunami estimates on Wake Island.

During model development, some geographical characteristics unique to Wake Island, such as the presence of a coral reef and the absence of shallow areas near the island, were factored into the grid design. After simulation of 10 historical events and 18 synthetic events, it becomes evident that these unique geographical features may be attenuating the impact of a tsunami on the island. The absence of shallow areas in the vicinity of the island probably prevents a wave from shoaling and gaining elevation as it approaches the coastline, and the presence of a coral reef surrounding the island serves as a natural breakwater, reflecting part of the tsunami energy away from the island. Minimum inundation was observed on the island, most of it located in the narrow channels separating Peale Island from Wake and Wilkes islands.

The presence of the shallow coral reef, however, makes it impossible to sub-sample the grid significantly while still resolving high-frequency waves generated by the reef. This results in Wake Island being one of the highest resolution forecast models developed, which translates into longer execution time, resulting in 4 hr of simulation time performed in just over 15 minutes on an Intel Xeon 3.6 GHz processor.

Table 3: Synthetic tsunami sources used in the forecast model robustness test for Wake Island.

# **Appendix A**

Development of the Wake Island tsunami forecast model occurred prior to parameter changes that were made to reflect modifications to the MOST model code. As a result, the input file for both the tsunami forecast model and the high-resolution reference inundation model in MOST have been updated accordingly. Appendix A1 and A2 provide the updated files for Wake Island.

## **A.1 Reference model \*.in file for Wake Island**

```
0.001 Minimum amplitude of input offshore wave (m)
5 Input minimum depth for offshore (m)
0.1 Input "dry land" depth for inundation (m)
0.0009 Input friction coefficient (n ★★2)
1 let a and b run up
100.0 max eta before blow up (m)
0.13 Input time step (sec)
360000 Input number of steps
25 Compute "A" arrays every nth time step, n=
3 Compute "B" arrays every nth time step, n=
300 Input number of steps between snapshots

## **Appendix C**

# **SIFT Testing**

### **C.1 Purpose**

Forecast models are tested with synthetic tsunami events covering a range of tsunami source locations. Testing is also done with selected historical tsunami events when available.

The purpose of forecast model testing is three-fold. The first objective is to assure that the results obtained with NOAA's tsunami forecast system, which has been released to the Tsunami Warning Centers for operational use, are identical to those obtained by the researcher during the development of the forecast model. The second objective is to test the forecast model for consistency, accuracy, time efficiency, and quality of results over a range of possible tsunami locations and magnitudes. The third objective is to identify bugs and issues in need of resolution by the researcher who developed the forecast model or by the forecast software development team before the next version release to NOAA's two Tsunami Warning Centers.

Local hardware and software applications, and tools familiar to the researcher(s), are used to run the Method of Splitting Tsunami (MOST) model during the forecast model development. The test results presented in this report lend confidence that the model performs as developed and produces the same results when initiated within the forecast application in an operational setting as those produced by the researcher during the forecast model development. The test results assure those who rely on the Wake Island tsunami forecast model that consistent results are produced irrespective of system.

### **C.2 Testing Procedure**

The general procedure for forecast model testing is to run a set of synthetic tsunami scenarios and a selected set of historical tsunami events through the forecast system application and compare the results with those obtained by the researcher during the forecast model development and presented in the Tsunami Forecast Model Report. Specific steps taken to test the model include:

1. Identification of testing scenarios, including the standard set of synthetic events, appropriate historical events, and customized synthetic scenarios that may have been used by the researcher(s) in developing the forecast model.

2. Creation of new events to represent customized synthetic scenarios used by the researcher(s) in developing the forecast model, if any.
3. Submission of test model runs with the forecast system, and export of the results from A, B, and C grids, along with time series.
4. Recording applicable metadata, including the specific version of the forecast system used for testing.
5. Examination of forecast model results from the forecast system for instabilities in both time series and plot results.
6. Comparison of forecast model results obtained through the forecast system with those obtained during the forecast model development.
7. Summarization of results with specific mention of quality, consistency, and time efficiency.
8. Reporting of issues identified to modeler and forecast software development team.
9. Retesting the forecast models in the forecast system when reported issues have been addressed or explained.

Synthetic model runs were tested on a DELL PowerEdge R510 computer equipped with two Xeon E5670 processors at 2.93 Ghz, each with 12 MBytes of cache and 32 GB memory. The processors are hex core and support hyperthreading, resulting in the computer performing as a 24 processor core machine. Additionally, the testing computer supports 10 Gigabit Ethernet for fast network connections. This computer configuration is similar or the same as the configurations of the computers installed at the Tsunami Warning Centers so the compute times should only vary slightly.

### C.3 Results

A forecast model for the U.S. territory of Wake Island was tested with NOAA's tsunami forecast system version 3.2. Testing was conducted with five synthetic scenarios and one historical tsunami event. Test results from the forecast system and comparisons with the results obtained during the forecast model development are shown numerically in Table C.1 and graphically in Figures C.1 to C.6. The results show that the forecast model is stable and robust, with consistent and high-quality results across geographically distributed tsunami sources and mega-event tsunami magnitudes. The model run time (wall-clock time) was under 19 min for 8 hr of simulation time, and under 10 min for 4 hr. This run time is within the 10 min run time for 4 hr of simulation time and satisfies time efficiency requirements.

Five synthetic events (there were no time series plots in the report for the CSSZ 89-98 case) were run on the Wake Island forecast model. The modeled scenarios were stable for all cases tested, with no instabilities or ringing. Results show that the largest modeled amplitude originating in the Kamchatka-Yap-Mariana-Izu-Bonin (KISZ 22-31) source, was 149.67 cm (Figure C1). Amplitudes greater than 100 cm were recorded for 1 out of 5 test sources. The smallest signal of 22.67 cm was recorded at a far-field Central and South American (CSSZ 102-111) source

(Figure C5). Direct comparisons, of output from the forecast tool with results of both the historical event (Kuril 2006) and available development synthetic events, demonstrated that the wave patterns were similar in shape, pattern, and amplitude.

Figure C.1: Response of the Wake Island forecast model to synthetic scenario KISZ 22–31 ( $\alpha = 29$ ). Maximum sea surface elevation for (a) A grid, (b) B grid, (c) C grid. Sea surface elevation time series at the C grid warning point (d). The lower time series plot is the result obtained during model development and is shown for comparison with test results.

Figure C.2: Response of the Wake Island forecast model to synthetic scenario ACSZ 56–65 ( $\alpha = 29$ ). Maximum sea surface elevation for (a) A grid, (b) B grid, (c) C grid. Sea surface elevation time series at the C grid warning point (d). The lower time series plot is the result obtained during model development and is shown for comparison with test results.

Figure C.3: Response of the Wake Island forecast model to synthetic scenario CSSZ 89–98 ( $\alpha = 29$ ). Maximum sea surface elevation for (a) A grid, (b) B grid, (c) C grid. Sea surface elevation time series at the C grid warning point (d). The lower time series plot is the result obtained during model development and is shown for comparison with test results.

Figure C.4: Response of the Wake Island forecast model to synthetic scenario CSSZ 102–111 ( $\alpha = 29$ ). Maximum sea surface elevation for (a) A grid, (b) B grid, (c) C grid. Sea surface elevation time series at the C grid warning point (d). The lower time series plot is the result obtained during model development and is shown for comparison with test results.

Figure C.5: Response of the Wake Island forecast model to synthetic scenario NTSZ 30–39 ( $\alpha = 29$ ). Maximum sea surface elevation for (a) A grid, (b) B grid, (c) C grid. Sea surface elevation time series at the C grid warning point (d). The lower time series plot is the result obtained during model development and is shown for comparison with test results.

Figure C.6: Response of the Wake Island forecast model to the Kuril 2006 event. Maximum sea surface elevation for (a) A grid, (b) B grid, (c) C grid. Sea surface elevation time series at the C grid warning point (d). The lower time series plot is the result obtained during model development and is shown for comparison with test results.

Table C.1: Table of maximum and minimum amplitudes (cm) at the Wake Island, United States Minor Outlying Islands warning point for synthetic and historical events tested using SIFT 3.2 and obtained during development.

Scenario Name	Source Zone	Tsunami Source	$\alpha$ [m]	SIFT Max (cm)	Development Max (cm)	SIFT Min (cm)	Development Min (cm)
<b>Mega-tsunami Scenarios</b>
